INTRODUCTION

Zika virus (ZIKV) disease is caused by an arthropod-borne virus of family Flaviviridae genus Flavivirus [1]. It is an arbovirus which can cause diseases in humans through a mosquito vector that was daytime-active A. aegypti and A. albopictus mosquitoes. It was first isolated from rhesus monkey in the Zika forest in Uganda in 1947 [2]. The virus is most prevalent and emerging pathogen that has recently causing serious disease around the world. Cases of ZIKV disease were reported in Micronesia in 2007 and then in French Polynesia in 2013. In Brazil the virus was introduced and associated with cases of microcephaly [3]. The virus has the potential to spread anywhere due to day time active mosquitoes capability to spread this virus. There is no case report about Zika Virus disease in Ethiopia [4]. In non-human primates (NHP), antibodies against Zika Virus have been reported both in wild and experimental animals in Borneo [5] and Uganda [6].

There is no case report of Zika virus disease in Ethiopia. Even though some studies and literatures review have been conducted on the Zika virus disease, the viral pathogen is re-emerging and spread into different countries of the World. Therefore the objects of this review is to review the epidemiology and public health importance of Zika virus disease.

EPIDEMIOLOGY AND ZOONOTIC IMPORTANCE OF ZIKA VIRUS DISEASE

Etiology and morphology of the virus

Zika virus is a mosquito-borne disease caused by single strand, non-segmented, positive-sense RNA virus of family Flaviviridae genus Flavivirus (Figure 1). The virus infects and cause disease in humans and non-human primates (NHP) [7].

The structure of the Zika virus is similar to other Flaviviruses. The other complex structure of the genome is terminus which is essential for causing disease in human. The protein composing the majority of the virion surface and is involved in the viral-host cell binding and membrane fusion during replication [9].

Geographical distributions and risk factor associated with diseases

The first virus isolation was case reported in human being in Uganda and Tanzania in 1954. Before 2007, there were reports of confirmed cases of Zika virus infection from the Africa and...
Southeast Asian continent. Later on in 2007, major epidemic occurred in Yap Island (Micronesia) where it affected about 5000 person [6], and also case report in Gabon [10].

In late 2015, the virus was reported for the first time in a number of countries in Central and South America with symptoms of microcephaly in affected parts of Brazil and now includes many Caribbean nations. However, the epicenter of the virus was Brazil and the virus soon spread to El Salvador, Honduras, Colombia, Venezuela and Costa Rica (Table 1).

The relationship of mosquito number with increased temperature is biological, that means it favors mosquitoes reproduction and increase their chance of contact with humans (for blood meal in case of female A. aegypti), which favor Zika transmission [22]. Risk factors associated with a disease are Vector related, Host related and Environmental related risk factors. The virus reservoir host is not completely identified and isolated, some studies suggest that, the reservoir host of Zika virus was primates. The other authors indicate the presence of anti-Zika antibodies in various animals including big mammals such as Zebras, Elephants and rodents in Pakistan [23]. The main source of Zika virus is infectious mosquitoes, mainly Aedes and secondary source is infected humans [24] (Figure 2).

Changes in climatic conditions, creates suitable conditions for mosquitoes by increasing its biting season and disease carrying mosquitoes will continue to bite as the climate warms. Weather conditions and global warming are important in occurrences of Zika Virus. For instance, El Niño is one of the factors that bring heavy rain which result in creating good opportunity for mosquito reproduction and multiplication site [25].

Transmission

The virus transmissions can be based on the numbers of primate and mosquitoes vectors [26]. The most common route of Zika virus diseases transmission is through the bite of mosquitoes of the family Culicidae and genus Aedes (hematophagous arthropods) during their blood meal [24]. Other modes of transmission are non-vector borne transmission through sexual intercourse, blood transfusion, organ transplantation and prenatal transmission has been reported. Sexual transmission of virus is a particular concern during pregnancy. Transmission of the virus from infected women to their sex partners has not been reported. However, transmission from infected men to women partner has been reported [18]. Transmission is possible through organ transplantation, mother-to-fetus during the period of pregnancy [19]. People traveled from areas with active Zika virus disease transmission to countries with free of Zika virus can transmit the disease to their sex partners.

Transmission in laboratory form A. aegypti mosquitoes to mice and a monkey was reported [18,24].

Pathogenesis

Zika virus has affinity towards human immature dendritic cells, dermal fibroblasts and epidermal keratinocytes. The virus may replicate in the midget. Zika virus disease enters the cells through receptors that are found on the surface of skin and nerve cells. After entrance the virus replicates and distribute to muscles, heart, central nervous system (CNS), and to fetus by crossing the placental barrier through blood vessels and lymphatic [27]. Viral replication in the host cells causes the release of type I interferon [28]. Inside the cells, they use host mechanism and finally cause apoptosis and autophagy of the cells. It causes damage to the eye of infants [29].

Zika virus diseases use certain means to defeat the host defense of the trophoblast and by attacking neuronal tissues, it cause neuronal abnormalities in the fetus [30]. Some study show that, the virus have affinity towards brain cells which was demonstrated when intraperitoneal injection of virus into mice the virus cross the blood brain barrier. Neurons and glial cells were infected by virus and producing intracytoplasmic inclusions called viral factories. One recent study revealed that, Zika virus

and man have a peptide in common which cause microcephaly and Guillain-Barré Syndrome (GBS) [31].

Clinical signs

The virus has an incubation period of 3-12 days [32]. In confirmed case of Zika virus, clinical signs include acute fever, maculopapular skin rashes, non-purulent conjunctivitis, arthralgia, headache, myalgia and asthenia [33]. There are also less evident signs like anorexia, abdominal pain, vomiting, diarrhea, burning sensation of sole and palm [34; 35]. Symptoms are usually self-limiting and may last for 4-7 days [32].

Diagnosis

Diagnostic testing for Flaviviruses is either direct detection of the virus RNA or detection of antibody responses to viral infection. In this manner virus can be detected from blood, other body fluids and tissues depending on stage of infection. For Zika virus, urine appears to have a higher viral detection than blood [36]. Reverse transcriptase–polymerase chain reaction (RT-PCR) methods used to detect both intact viral particles and replicating viral RNA inside cells. Serological tests for Zika virus on immunoglobulins (IgG and IgM) can be done in order to confirm the presence of neutralizing antibody infection [37].

Treatment

Zika Virus disease is relatively mild and requires no specific treatment. People sick with this disease should get plenty of rest, drink enough fluids and treat pain and fever with common medicines like acetaminophen (paracetamol), and antihistamine for pruritic rash is necessary. Other non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided until dengue can be ruled out to reduce the risk of hemorrhage [37]. It is also important to understand the link

Prevention and control

Prevention and control relies on reducing mosquitoes through reduction of breeding sites and reducing contact between mosquitoes and people. Contact between mosquito and people can be prevented by using physical barriers such as window nets, closed doors and windows [6]. Integrated management of the Aedes mosquitoes through biological and chemical control is safe and cost effective. Integrated vector management systems are the most important prevention and control method [22]. In case of biological control, larvivorous fish are recommended for control of Aedes aegypti in large water bodies or large water Containers.

Endotoxin producing bacteria, Bacillus thuringiensis serotype H-14 has been an effective mosquito control agent [24].

Insecticide which can kill both adult and larvae are import control method in developing countries like Ethiopia. Larvicides include temephos and organophosphate compound. Adulicide recommend for the control of adult Aedes mosquito is Pyrethrum sprays [38].

CONCLUSION

In conclusion, Zika virus disease is not a life threatening but it is serious disease because of the birth defect. It is important to understand the link between microcephaly and the disease because the link is used to develop vaccine. Therefore, People should aware about the transmission, prevention and control of diseases to avoid exposure of pregnant women to the vector and community water gathering around the house.
