Abstract

Introduction: Ischemic stroke has been associated with stunned myocardium and neurogenic pulmonary edema (NPE). We studied a population of patients with large vessel brainstem ischemic stroke to see if there was an increased risk of pulmonary edema associated with strokes in this region independent of myocardial stunning.

Hypothesis: Large vessel ischemic strokes of the brainstem are associated with neurogenic pulmonary edema and occur independently of myocardial stunning.

Methods: This is a retrospective case control study of 1,278 patient admissions. Two hundred ten patients were identified with large vessel ischemic stroke or transient ischemic attack (mean age 65 years, 55% female, 50% black). Infarction locations included: brainstem (N=22), right middle cerebral artery involving the insula (N=38), left middle cerebral artery involving the insula (N=37), and transient ischemic attack (N=113). Multivariate logistic regression models for presence of echocardiographic wall motion abnormalities, QTc-interval prolongation, elevated serum troponin, and pulmonary edema were developed to examine the relative contribution of stroke location and markers of cardiopulmonary dysfunction to each respective outcome, controlling for patient characteristics.

Results: Large vessel brainstem stroke was associated with pulmonary edema (adjusted OR 29.23, 95% CI 1.90-449.51) but not cardiac abnormalities. Large vessel left middle cerebral artery stroke was also associated with pulmonary edema (76.44, 6.93-843.54) as well as QTc-interval prolongation (4.55, 10.77-19.24). Large vessel right middle cerebral artery stroke was associated with pulmonary edema (10.88, 1.02-116.70) as well as elevated serum troponin (10.51, 1.71-64.82).

Conclusion: In a retrospective case control study, large vessel brainstem stroke was associated with the development of pulmonary edema independent of cardiac abnormalities associated with myocardial stunning, suggesting a separate brainstem pathophysiologic mechanism which directly affects the lungs but not the heart.

INTRODUCTION

Over 790,000 strokes occur annually in the United States, making it the fourth leading cause of death and the leading cause of disability in people over the age of 65 [1]. Pulmonary and cardiac complications after stroke are common. The association of ischemic stroke with electrocardiographic change and elevated cardiac enzymes has been known for decades [2-4]. The classic triads of findings for neurogenic myocardial stunning are transient left ventricular wall motion abnormalities, electrocardiographic abnormalities and elevation in myocardial enzymes in the serum in the absence of coronary artery disease [5]. The physiological mechanisms underlying these associations are not fully understood. They are thought to involve sympathetic hyperactivity and possibly anatomic inhibition due to insular cortical injury [6-8]. Localization of ischemic stroke to the insula and the parietal lobe has been associated with fatal arrhythmias in animal models and human studies [7-9].

Respiratory failure occurs in 5-10% of patients with acute ischemic stroke, most often secondary to aspiration and decreased airway protection. Pulmonary parenchymal disease has been observed as a direct consequence of centrally mediated injury due to neurogenic pulmonary edema (NPE) [9,10]. NPE has been noted as a complication of a variety of neurological syndromes, including basilar artery thrombosis and intracerebral...
hemorrhage [9-11]. The anterior and posterior cerebrovascular distributions have both been implicated in NPE [9,11,12].

It is unknown how often acute pulmonary edema noted in the setting of ischemic stroke occurs independently or as a result of cardiac dysfunction. It is also unknown if there is a relationship of particular cerebrovascular distributions to particular patterns of cardiac and/or pulmonary dysfunction in ischemic stroke. Here we describe a retrospective review of patients treated at a tertiary stroke center for large vessel ischemic stroke, to explore the association of the cerebrovascular distribution of infarction to pulmonary edema and cardiac function derangements as measured by echocardiography, elevated cardiac enzymes and echocardiography. We hypothesized that we would find an association between large vessel ischemia in the brainstem and pulmonary edema occurring independently of cardiac abnormalities associated with myocardial stunning.

PATIENTS AND METHODS

A retrospective review was performed on all patients admitted or transferred to the cerebrovascular neurology service at Johns Hopkins Hospital from June 2009 through June 2011. Clinical data obtained included: age; gender; race; and medical history of diabetes, hypertension, hypercholesterolemia, smoking, arrhythmia, atrial fibrillation, coronary artery disease, heart failure, diabetes and prior stroke or transient ischemic attack (TIA). Past medical history was recorded as per documentation in the medical record at time of admission.

All patients >17 years of age admitted to the Johns Hopkins Hospital cerebrovascular service were included, whether or not they died while admitted. Patients were included if they had a discharge diagnosis of TIA (control group) [13]; ischemic stroke of the right or left middle cerebral artery (RMCA or LMCA); or basilar artery ischemic stroke, stenosis or occlusion. All other patients were excluded, including those who had ischemic strokes in multiple cerebrovascular distributions. To ensure inclusion of patients with large vessel middle cerebral artery infarction, of those patients with discharge diagnosis of ischemic stroke of the RMCA or LMCA, only those patients with radiographic findings consistent with infarction of the insular cortex were included. To ensure inclusion of patients with large vessel brainstem infarctions, of those patients with discharge diagnosis of basilar artery ischemic stroke, stenosis or occlusion, only those with radiographic findings consistent with infarction within the midbrain, pons and/or medulla in the setting of basilar artery stenosis or occlusion were included.

Imaging and laboratory data included: echocardiogram reports; electrocardiogram (EKG) reports upon admission and 48 hours after admission; initial and peak serum troponin levels; chest radiographs during admission. Heart failure was defined as an ejection fraction of ≤ 35% as measured by echocardiogram [14]. Cardiac wall motion abnormalities were documented by cardiologist-based interpretation of echocardiogram. Troponinemia was defined as >0.06 ng/mL, per institutional clinical laboratory designation. Nonspecific ST segment abnormalities and arrhythmias were determined from the final cardiologist report of EKG. Corrected QT (QTc) interval prolongation was defined as >460 ms per EKG report. The presence or absence of pulmonary edema was determined by review of chest radiographs within 96 hours of admission, when available. These were reviewed by physician reviewers blinded to patient diagnosis and study hypothesis (T. C. and D. V.) using previously established criteria [15].

STATISTICAL ANALYSIS

For continuous variables, medians with interquartile range (IQR) and means with standard deviations (SD) were calculated. For categorical variables, frequencies were measured. Group differences for continuous variables were tested by one-way analysis of variance with Bonferroni’s adjustment for multiple comparisons. The X² test for independence or Fisher’s exact test was used to examine group differences for categorical variables. Univariate analyses were performed to assess for significant risk factors for development of pulmonary edema. Multivariate logistic regression analyses were performed with outcomes of interest (i.e. pulmonary edema, echocardiographic wall motion abnormalities, presence of elevated serum troponin, and QTc-interval prolongation) serving as the dependent variables. When clinical data was missing, the documented diagnosis was used based on clinical examination or report of clinical data at time of admission.

For each multivariate logistic regression model, patient characteristics including age ≥ 57 years [16], history of atrial fibrillation, history of coronary artery disease, history of diabetes mellitus, history of heart failure, history of hypertension, history of smoking, and stroke location were included as independent variables and controlled for. In addition, diagnostic results indicative of cardiopulmonary dysfunction including presence of wall motion abnormalities on echocardiogram, arrhythmia on admission EKG, QTc prolongation on admission EKG, presence of pulmonary edema, and elevated serum troponin were included and controlled for as independent variables except when the dependent variable of interest for a respective multiple logistic regression model. Collinearity diagnostics were performed to assess for intercorrelations among independent variables. The amount of variation in the dependent variable explained by each respective model was assessed using Cox & Snell R Square and the Nagelkerke R Square tests. Goodness-of-fit of each multivariate logistic regression model was assessed by Hosmer and Lemeshow’s test (H-L). Significance of regression coefficients to respective logistic regression models were assessed using Wald’s test. Two-tailed statistical significance was assessed at the p<0.05 level. All statistical analyses were performed using the SPSS (version 22, IBM, Armonk, NY) statistical package while figures were made using the Prism (version 5, GraphPad, San Diego, CA) statistical package.

RESULTS

Clinical characteristics

We completed a review of 1,278 patient records. There were 210 patients with large vessel ischemic stroke or TIA identified and included in our analysis. Of these patients, 55% were female, 50% were black, 75% had a history of hypertension and their average age was 63.5 years (SD 15.9). Twenty-two patients had brainstem stroke in the setting of basilar occlusion or stenosis, 38 patients had large vessel right middle cerebral artery (RMCA)
strokes involving the insula, 37 patients had large vessel left middle cerebral artery (LMCA) strokes involving the insula, and 113 TIA control patients were identified. The large vessel brainstem stroke group included two patients with isolated medullary infarct, ten patients with isolated pontine infarct, and ten with infarction of multiple brainstem structures. With the exception of history of atrial fibrillation ($\chi^2$ (3,$N=208$) =14.75, $p=0.002$) and history of heart failure ($\chi^2$ (3,$N=208$) =10.72, $p=0.01$), patient groups were similar in terms of age; gender; race; history of prior stroke or TIA, diabetes, smoking and hypercholesterolemia (Table 1).

**Pulmonary evaluation**

Chest radiographs were available for review for 65 TIA, 28 RMCA, 31 LMCA, 19 brainstem stroke patients. The presence of pulmonary edema was determined based on review of available chest radiographs within 96 hours of admission [15]. For all other patients, pulmonary edema assessment was based on pulmonary examinations and available chest radiograph reports at time of admission.

The proportion of patients with pulmonary edema varied across the four groups ($\chi^2$ (3,$N=210$) =52.02, $p=0.0001$, Figure 1A). A greater proportion of brainstem (0.50) and LMCA (0.43) stroke patients had pulmonary edema compared to both the TIA control (0.02) and RMCA stroke (0.24) groups.

Of the potential predictors for presence of pulmonary edema after large vessel ischemic stroke, only patient age $\geq$ 57 years, patient history of atrial fibrillation, patient history of heart failure, stroke location, stroke etiology and elevated serum troponin were predictive (Table 2). The multivariate logistic regression model for presence of pulmonary edema explained between 36.7% and 53.5% of the variance in development of pulmonary edema, correctly classifying 81.4% of cases compared to baseline prediction rate of 73.5%, and fit the observed data well (H-L $\chi^2$ (8) =5.50,$p=0.70$) without evidence of intercorrelations among the independent variables. As shown in Table 3, having a LMCA stroke (adjusted OR 76.44, 95% CI 2.17-42.78) and patient history of coronary artery disease (8.44, 2.04-34.93) were predictive of the presence of wall motion abnormalities on echocardiogram during admission.

**Echocardiography**

Echocardiographic images were obtained from 83 TIA, 35 RMCA, 31 LMCA and 14 brainstem stroke patients. There was no difference in proportion of patients with an ejection fraction $\leq$ 35% ($\chi^2$ (3,$N=167$) =3.93, $p=0.27$). Similarly, there was no difference in proportion of patients with new diagnosis of heart failure or decreased ejection fraction from baseline across groups ($\chi^2$ (3, $N=167$) =5.15, $p=0.16$). However, the proportion of patients with cardiac wall motion abnormalities on echocardiogram by cardiologist interpretation varied across groups ($\chi^2$ (3, $N=163$) =9.04, $p=0.03$) with a greater proportion of patients with RMCA stroke (0.34) than TIA (0.13) and brainstem stroke (0.07). There was no difference in proportions between the RMCA and LMCA (0.26) stroke groups.

The multivariate model for echocardiographic wall motion abnormalities explained between 31.4% and 45.8% of the variance in having cardiac wall motion abnormalities on echocardiogram, correctly classifying 83.3% of cases, compared to baseline prediction rate of 73.5%, and fit the observed data well (H-L $\chi^2$ (8) =9.20, $p=0.33$) without evidence of intercorrelations among the independent variables. Stroke location made a significant contribution to the model. Only patient history of heart failure (adjusted OR 9.63, 95% CI 2.17-42.78) and patient history of coronary artery disease (8.44, 2.04-34.93) were predictive of the presence of wall motion abnormalities on echocardiogram during admission.

**Serum troponin**

Serum troponin levels were measured for 65 TIA control patients, 27 RMCA, 28 LMCA and 12 brainstem stroke patients and varied significantly across groups ($\chi^2$ (3, $N=210$) =20.43, $p=0.0001$). A smaller proportion of TIA patients (0.05) had elevated serum troponin levels than RMCA (0.41), LMCA (0.32) and brainstem (0.33) stroke patients.

The multivariate logistic regression model for presence of elevated serum troponin explained between 26.8% and 40.8% of the variance in having an elevated serum troponin, correctly classifying 84.3% of cases compared to baseline prediction rate of 77.5%, while fitting the data well (H-L $\chi^2$ (8) =4.71,$p=0.79$)

Table 3: Multivariate Logistic Regression Model for Prediction of Pulmonary Edema. Stroke location, with TIA serving as the reference category, contributed significantly to the multivariate logistic regression model predictive of development of the presence or absence of pulmonary edema. Age>57 years (adjusted OR 1.40; 95% CI 1.40-7.68), history of atrial fibrillation (1.81, 0.29-11.60), history of coronary artery disease (0.93, 0.18-4.87), history of diabetes mellitus (0.41, 0.09-1.76), history of heart failure (5.22, 0.94-28.96), history of hypertension (1.78, 0.34-9.24), history of smoking (0.43, 0.10-1.86), wall motion abnormality noted on echocardiogram during admission (0.50, 0.11-2.33), troponinemia (3.42, 0.79-14.71), presence of arrhythmia on admission EKG (0.39, 0.05-2.77) and QTc prolongation (>460ms) on admission EKG (0.75, 0.18-3.17) did not contribute significantly to this multivariate logistic regression model.

without evidence of intercorrelations among the independent variables. Only having a RMCA stroke (adjusted OR 10.51; 95% CI 1.71-64.82) was predictive of having an elevated serum troponin level.

Electrocardiography

Electrocardiograms were performed on 106 TIA control, 37 RMCA, 36 LMCA and 22 brainstem stroke patients. The proportion of patients with prolonged QTc-intervals (>460ms) was different across groups (χ² (3, N=201) =14.92, p=0.002), with the proportion within both the RMCA (0.43) and LMCA (0.50) stroke groups being greater than for the TIA (0.20) and brainstem stroke (0.32) groups. The proportion of patients with prolonged PR-intervals (>200ms; χ² (3, N=170) =7.62, p=0.06), arrhythmia (χ² (3, N=201) =6.46, p=0.09), abnormal intraventricular conduction (χ² (3, N=201) =2.58, p=0.46), or any ST-segment abnormality (χ² (3, N=201) =0.91, p=0.82) did not vary across groups.

The multivariate logistic regression model for presence of a prolonged QTc-interval on admission EKG explained between 26.3% and 36.0% of the variance in having a prolonged QTc-interval, correctly classifying 73.5% of cases compared to baseline prediction rate of 63.7%, while fitting the data well (H-L χ² (8) =8.09,p=0.43) without evidence of intercorrelations among
the independent variables. Only having a LMCA stroke (adjusted OR 4.55, 95% CI 10.77-19.24) was predictive of having QTc-interval prolongation.

**Myocardial dysfunction**

The proportion of patients with either wall motion abnormalities on echocardiogram, elevated serum troponin, arrhythmia on admission EKG and/or QTc-interval prolongation on admission EKG varied across groups ($\chi^2 (3, N=210) =16.87$, $p=0.001$). Both RMCA (0.68) and LMCA (0.60) stroke groups had proportions greater than brainstem stroke (0.55) and TIA (0.35) groups (Figure 1B).

**DISCUSSION**

In a limited retrospective case control study of patients treated at a single tertiary medical center, large vessel ischemic stroke of the midbrain, pons, and/or medulla was associated with the development of pulmonary edema independent of evidence of cardiac abnormalities typically associated with myocardial stunning. In contrast, both large vessel RMCA and LMCA strokes with involvement of respective insular cortex were associated with pulmonary edema as well as cardiac abnormalities associated with myocardial stunning [5]. This suggests separate brainstem pathophysiological mechanisms for pulmonary edema with effects on the lungs but not the heart.

Neurogenic pulmonary edema and cardiac derangements, including stunned myocardium, have long been associated with increased mortality in a variety of neurological diseases, from seizures and trauma to hemorrhagic and ischemic stroke [9,17]. Catecholamine surge in the setting of injury to the diencephalon and brainstem is thought to cause activation of both $\alpha$- and $\beta$-adrenergic receptors within both the pulmonary venous bed and myocardium, and neurogenic pulmonary edema independent of myocardial dysfunction has been felt to be a relatively rare phenomenon [9,10]. Specifically, sympathetic activation has been suggested to play a primary role in precipitating raised hydrostatic pressure and elevated vascular permeability in the pulmonary venous bed, similar to that seen in acute respiratory distress syndrome (ARDS) [11,18-21]. Here we present findings which suggest that in ischemic stroke of the brainstem, pulmonary edema can occur in the absence of cardiac derangement and stunned myocardium.

The relationship of stroke location (i.e. whether of the anterior or posterior circulation, laterality) to the development of cardiac derangements and neurogenic pulmonary edema following stroke is an open question. Cortical involvement in the development of cardiac derangements (e.g. dysrhythmia, QTc prolongation, heart failure) following ischemic stroke has been proposed to rely on connectivity of cortical regions, such as the medial prefrontal cortex and insular cortex, with the hypothalamus, midbrain, pons and medulla [22]. The laterality of infarction, whether right hemispheric or left, has been of unclear significance to the development of cardiac derangements and sudden death [23-25]. Similarly, direct injury to the hypothalamus, nucleus tractus solitarius and area postrema and their respective sympathetic projections to the hypothalamus and spinal cord have been implicated in the generation of isolated neurogenic pulmonary edema [9]. In animal model experiments, severe hypertension and neurogenic pulmonary edema have been induced by lesions to the hypothalamus as well as by irritation of the tractus solitarius nuclei of the medulla while increased cardiac output, peripheral vascular resistance and hypertension have been induced by unilateral stimulation of the area postrema of the medulla [9,26,27]. In animal models using phenolamine, an alpha-adrenergic antagonist active at the postganglionic adrenergic receptors, pulmonary edema has been prevented [26,27]. Hexamethonium, a preganglionic nicotinic acetylcholine receptors blocker caused reduction of serum catecholamine levels, reversal of hypertension, preservation of cardiac function, and prevention of hemorrhagic pulmonary
edema after pharmacological ablation of the nucleus tractus solitarius [28].

There are isolated case reports of treatment responsive neurogenic pulmonary edema treated with phenolamine to interrupt cyclical hemodynamic instability and hypoxic respiratory failure. This has been reported in the setting of progressively declining urine catecholamine levels [29]. Fulminant neurogenic pulmonary edema has also been treated with prone positioning in ventilated patients [11].

These experimental and clinical observations suggest cardiopulmonary compromise in the setting of central nervous system injury. This study suggests neurogenic pulmonary edema in ischemic stroke can occur in the setting of large vessel infarction of the brainstem. This occurs independently of concomitant cardiac involvement as indicated by elevated serum troponin levels, EKG changes, and altered wall motion on echocardiography. This pattern of pulmonary edema independent of cardiac involvement associated with large vessel brainstem infarcts was markedly different from patterns observed in large vessel cortical strokes involving the RMCA and LMCA which were also associated with objective signs of stunned myocardium.

This study is limited by its retrospective case-control design of data from a single tertiary facility with inherent potential for selection and recall bias including incomplete clinical data available for review. This also includes the effect of lead-time bias for the onset of pulmonary edema and variability in treatment across cases [9,30]. Ischemic stroke size may have varied between groups and was not controlled for in this study. The large confidence intervals for multivariate analyses likely reflect the small sample size of this study, warranting larger, prospective study. Prospective multi-center studies of the pulmonary and cardiac derangements associated with ischemic stroke would help to clarify the temporal relationship of infarction with cardiopulmonary derangements.

CONCLUSION

In patients with large vessel brainstem infarction, unlike in patients with large vessel RMCA and LMCA strokes involving the insula, pulmonary edema can occur independent of myocardial stunning as analyzed by separate and composite cardiac endpoints including cardiac dysfunction, elevations of troponin and abnormalities of electrical conduction. This suggests that neurogenic pulmonary edema can be caused by ischemia of brainstem structures independent of cardiac dysfunction. Confirmation of these findings in a prospective analysis assessing the region of cerebrovascular involvement as well as brainstem structural involvement and the risk of neurogenic and cardiogenic pulmonary edema are required.
